INTRODUCTION

The study area is located at the southern end of a large, quasi-circular topographic low in central eastern Oregon known as the Harney Basin (Figure 1). Limits of the study area were arbitrarily determined according to the boundaries of available U.S. Geological Survey (USGS) topographic maps as $43^{o}00'$ on the south, $43^{o}30'$ on the north, $118^{o}30'$ on the east, and $119^{o}30'$ on the west. This study, performed under U.S. Department of Energy Contract No. DE FC07-79ET27220, was undertaken to estimate the geothermal potential of the area, using various methods including compilation of existing data, reconnaissance geologic mapping, lineament analysis, well and spring geochemistry, and accrual of geothermal-gradient data.

Geographically, the study area is comprised of a roughly circular, relatively flat,closed drainage basin that covers an area of 21,000 km^2 (8,100 mi^2). Included within the basin are volcanic mounds surrounded by mountainous highlands. Drainage within the basin is into several closed desert lakes, including Malheur, Harney, and Mud Lakes, through Silvies River from the north, Donner und Blitzen River from the south, Warm Springs Creek from the west, and Malheur Slough from the east. Total relief within the basin is less than 9 m (30 ft), total relief in the highlands more than 500 m (1,600 ft). The only population centers are the small farming communities of Crane, Princeton Post Office, and Diamond, all in the eastern portion of the study area. The remainder of the southern basin is comprised of swampy bird habitats, cattle ranches, and range land.

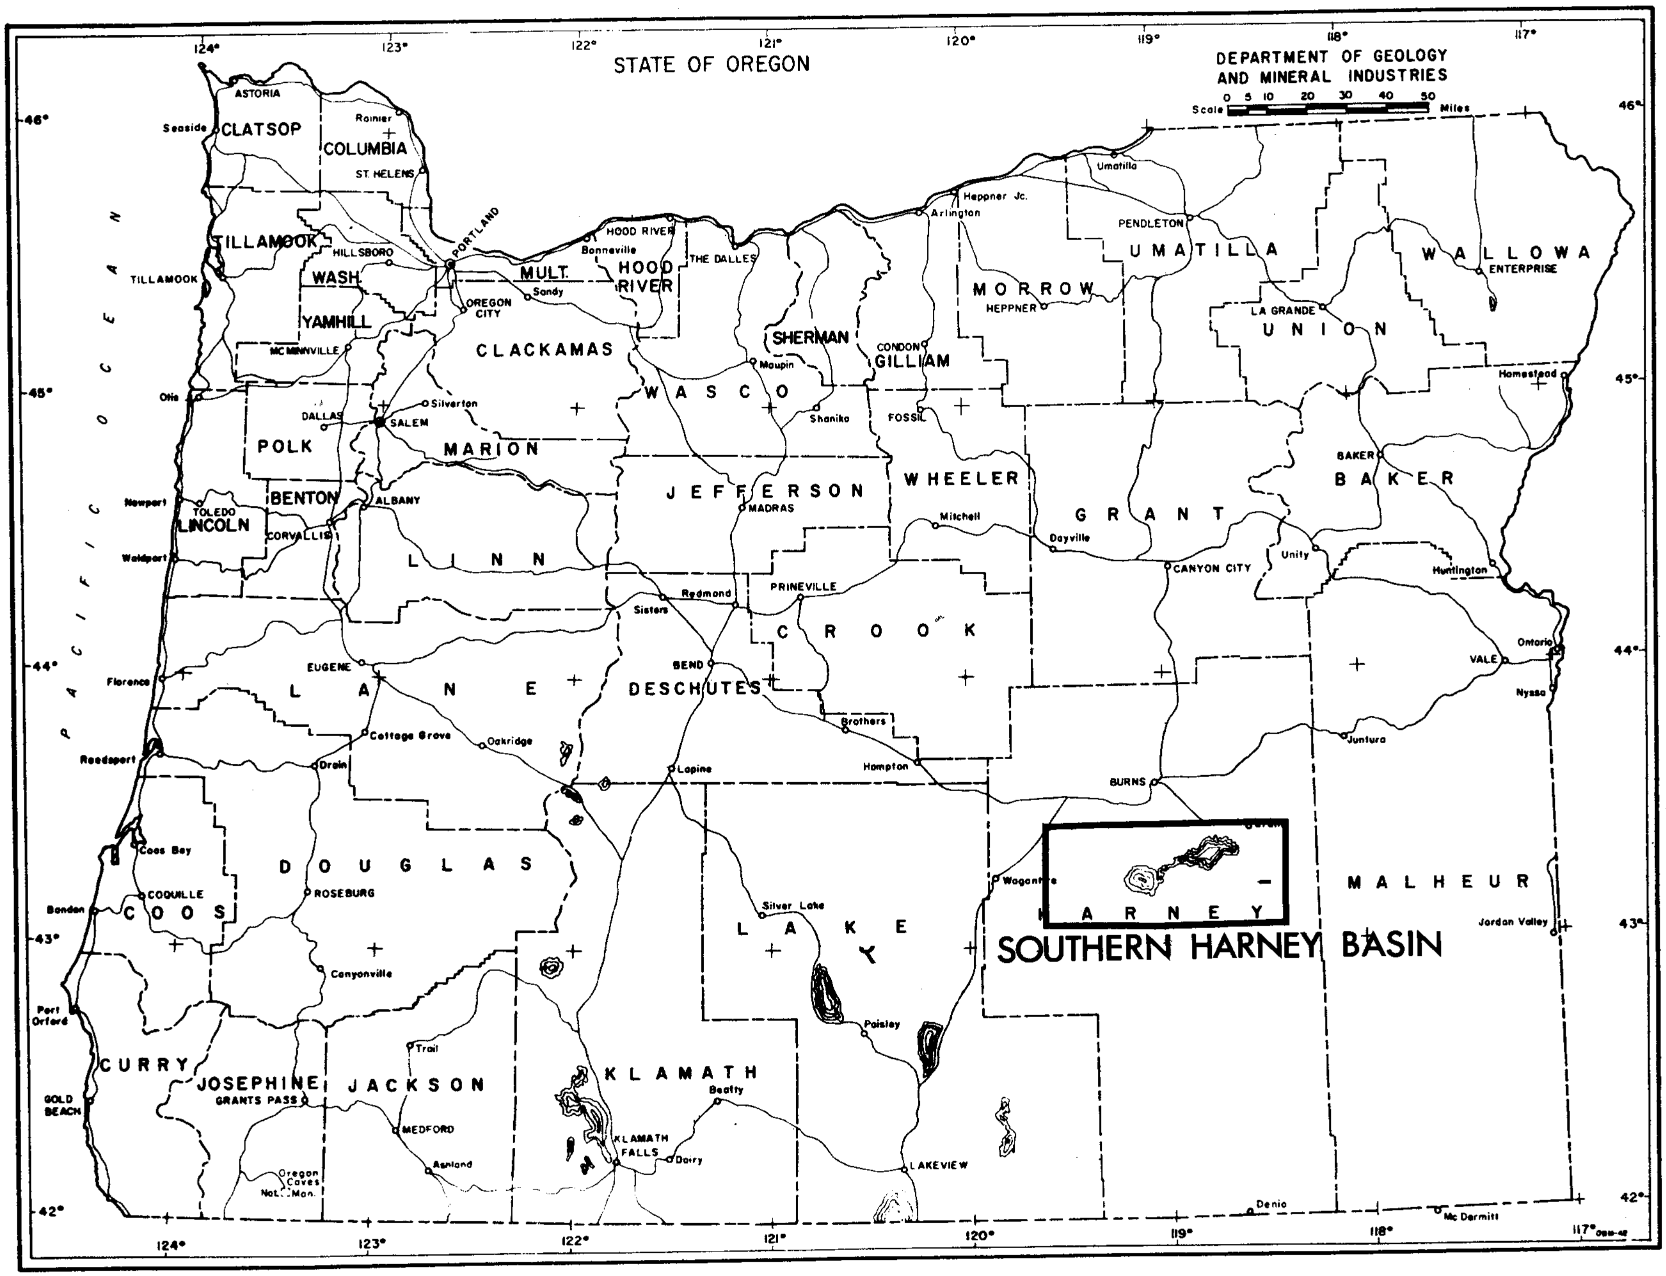

Figure 1: Map showing location of study area.

GEOLOGY

Introduction

The geologic study of the area (Plates I-IV) consisted of (1) a field check and minor revisions of a study of the western half of the area by Parker (1974), and (2) an original reconnaissance study of the eastern half of the area during the fall of 1979 and spring of 1980. Quadrangles mapped in reconnaissance include the Crane and Lawen 15-minute quadrangles and the Jackass Butte, Jackass Butte N.E., Diamond Swamp, Diamond, Adobe Flat, Barton Lake, and Coyote Buttes 7½-minute quadrangles. Lithologies were based on hand specimen identifications, limited K/Ar ages (Table 1), and available bulk chemistry (Table 2). Areal extents of various units and specific points were located by using Brunton compass and pacing; data were plotted on USGS quadrangle maps without the aid of aerial photos.

Volcanic stratigraphy

The geology of the southern Harney Basin is comprised of a framework of two flat-lying, extensive, late Miocene ash-flow sheets onlapping a regional unit of early Miocene flood basalts. The ash flows, in order of increasing age, are the Rattlesnake and Devine Canyon Ash-flow Tuffs (Walker, 1979). They are separated by discrete fluvial-lacustrine sedimentary units, flood basalts and their vents, and silicic intrusions. Trace-element studies by Parker and Armstrong (1972) indicate that the ash-flow tuffs, the silicic intrusives, and the related mafic flows of the area form a bimodal compositional assemblage. Though detailed relationships are unclear at this time, at least one and possibly two calderas are present in the study area, one located beneath Malheur and Harney Lakes being the source of the Rattlesnake ash-flow sheet (Blank, 1974; Walker, 1979). The oldest unit recognized in the field is that of the early Miocene flood basalts found along the eastern

portion of the mapped area. Dates in adjacent areas indicate ages of 12.1 to 20.2 m.y.; a date taken for this report from Jackass Butte in the south-central portion of the map yielded an age of 16.7 m.y. The youngest rocks are the basalts associated with the Holocene Diamond Craters vent area for which there is a reported date of 15,000±2,000 years, as determined by hydration rind method (Norm Peterson, 1980, personal communication). These youngest rocks directly overlie a second set of young flood basalts which issued from vents mapped immediately south of Malheur Lake along what is probably a ring fracture zone of the caldera mentioned above. A third group of young lavas are the extensive flood basalts which issued from the Dog Mountain-Freeman Butte area. They have been eroded to form reverse topographic features such as Wrights Point and were dated by Parker (1974) at 2.6 to 2.8 m.y. The extensive age determinations available for this study (Table 1) indicate a strong relationship between age of basaltic eruption, age of silicic event, and, in two cases, age of ash-flow eruption. These age/modal relationships are shown in the time-rock charts on the accompanying geologic maps (Plates I-IV). There are still, however, numerous small phreatic and subaqueous vents which do not have lavas that can be dated and whose absolute age relationships, therefore, are unclear and which may, in some cases, be of very young age.

Structural geology

Faulting in the southern Harney Basin follows two general trends. The first is the Basin-Range trend (approximately north-south) which occurs in only a limited area immediately north of Crane in the extreme northwest corner of the map. The age of this normal faulting is not clear. However, it does cut the youngest unit present (6.1 m.y.).

The second trend is the Brothers fault zone trend (N.25^{o}-35^{o}W.), which dominates the remainder of the map and cuts all bedrock units present, including the 15,000-year-old Diamond Craters. All motion in this trend appears to be dip-slip. However, the presence of lateral-slip or oblique-slip faulting cannot be ruled out. Several authors (McLeod and others, 1975) feel the Brothers fault zone may be, in fact, the surface expression of a right-lateral wrench system at depth.

The intersection of the two fault trends is in the southeast corner of the map (Plate IV), in the Riddle Mountain-Diamond Craters area (a portion of which remains unmapped). This area is a fault-shattered zone which shows considerable coxcomb-like faulting on small spacing with short-period monoclinal folding and rotating of the discrete blocks between individual faults. Two adjacent structural domes also occur in this area, connected from dome crest to dome crest by a horst-like fault ridge and separated by one, and possibly two, small structural basins. At the leading edge of this zone is the Diamond Craters vent area, which, in itself, is cut by several faults of the Brothers trend. Structural interpretation of this complex area is difficult. It seems that the structures are controlled by a local compressional regime and that Diamond Craters is, in some way, closely related to the intense faulting and folding.

Folding in the southern Harney Basin, with the exception of that previously described, is generally in the form of broad, shallowly dipping anticlines and synclines plunging toward the center of the basin. One such fold in the Crane area plunges west toward the basin. Here, the older ash-flow units and basalts have been down-folded and infilled with 6.1-m.y.-old basalts. This age is slightly younger than the 6.5-m.y. age of the Rattlesnake Ash-flow Tuffs (Walker, 1979), and the down-folding may have been in response to caldera formation and subsequent volume loss.

A lineament study (Plate V) prepared for this report shows a general one-to-one correspondence of structural trends with the mapped fault trends. It also shows a number of lineaments which cross the alluvial-filled basin but which could not be traced through geologic mapping.

Individual blocks within the fault zones, in general, dip back toward the center of the basin. However, during the mapping project, a number of blocks that dipped away from the basin were found. The basin itself has been formed by downwarping which began during middle to late Miocene (Walker, 1979). The process was caused by loss of material through volcanic eruption of the extensive ash-flow sheets and numerous flood basalts and, to a lesser extent, by the loss of material volume due to loss of stored heat (Blackwell, 1980, personal communication).

GEOPHYSICS

The only available geophysical survey for the southern Harney Basin is an aeromagnetic survey flown in 1972 by the USGS (Plate VI). Because of the dramatic contrast between the relative magnetic susceptibilities of mafic and silicic lavas, a good correlation between structure and rock type and magnetic trends is clearly apparent. On the eastern portion of the map and correlative to the mapped Basin-Range fault trend discussed earlier in this report, a strong north-south magnetic trend occurs. Anomalies, both maxima and minima, elongated in a north-south direction along this trend probably indicate the numerous juxtaposed fault blocks which were found during this study. The central portion of the aeromagnetic map is dominated by intensive maxima over Diamond Craters and Coyote Buttes and a large oval minimum over Malheur Lake. The maxima are probably due in part to localization of mafic vent material at or near the surface at Diamond Craters and Coyote Buttes. Surface mapping also indicates a number of small, isolated phreatic cones and vents and extensive silification which may indicate a mafic intrusive buried beneath the ridge at Coyote Buttes. The oval minimum seen between the two maxima is in all likelihood the site of the caldera for the Rattlesnake Ash-flow Tuff (Blank, 1974), which erupted approximately 6.5 m.y. ago (Walker, 1979). This minimum is cut by a northwesterly trending ridge of magnetic maxima which may be a zone of post-Rattlesnake faulting. The remainder of the map is dominated by the Brothers fault zone trend with isolated maxima and minima centered over mapped silicic and mafic volcanic vents.

Detailed interpretation of structures and geothermal systems cannot be made on the basis of a single aeromagnetic survey. Proposals for future geophysical studies are included in the Conclusions and Recommendations of this report.

WATER CHEMISTRY

During the period of this study, 22 wells and springs were sampled and their waters analyzed. Together with existing published analyses (U.S. Geological Survey and Oregon Department of Geology and Mineral Industries, 1979; Leonard, 1970), a total of 28 analyses were available for evaluation (Table 3). These analyses were then used to calculate minimum reservoir temperatures (Table 4), using standard formulae for geothermometry. The methods used in these analyses, together with references, are included in this report as Appendix A. Published reports on the hydrology of the Harney Basin (Piper and others, 1939; Leonard, 1970) show a considerable number of thermal anomalies. However, many of these wells and springs either could not be located, were not flowing at the time of the study, or were inaccessible because of weather conditions or the owners' refusal to allow sampling.

Sampling temperatures during field collection ranged from 76^{o}C and 67^{o}C for Crane Hot Springs and Harney Lake Hot Springs, respectively, down to 15^{o}-20^{o}C for wells and springs bordering Harney Lake. The natural water of the study area can best be described as generally high in magnesium, calcium, and boron, and low in chloride and bicarbonate. On the basis of preliminary evaluation of the available data, two, and possibly three, groups of waters are recognized. The first are from the wells and springs near the town of Crane and the surrounding area and appear to have moderate total dissolved solids (184-564 mg/l), high Ca:Mg ratios for the cooler waters (4.1-13), consistently moderate silica throughout the sampling temperature range (56.2-93.2 mg/l) and consistently high amounts of calcium for the cooler waters (13-28.6 mg/l). Calculated minimum reservoir temperatures for these waters (Table 4) are also consistently in the 90^{o}-120^{o}C range. Geologic control for these waters is difficult to define in relation to the reconnaissance study;

however, preliminary examination seems to indicate the waters are controlled by intersection of Basin-Range faulting and the Rattlesnake collapse caldera, previously described in the section on geology. The difference in chemical character of various Harney Basin waters is probably due to a difference in chemical composition of rocks in the recharge zone and duration of subsurface circulation.

The second group of waters is from the area surrounding Harney Lake in the southwest corner of the study area. These waters are generally higher in total dissolved solids (233-10,616 mg/l), lower in Ca:Mg ratios (0.45-6.1), inconsistent in silica concentrations through the sampling temperature range (29.4-120 mg/l), lower in calcium content (0.1-37 mg/l), and slightly inconsistent in calculated minimum reservoir temperatures. Geologic control for these waters is likewise difficult to define; however, preliminary indications seem to show they are controlled by the intersection of the Rattlesnake collapse caldera and the Brothers fault zone structural trend. Differences in chemical constituents are probably due to the relative abundance of sediments and silicic rocks through which the water must circulate before it reaches the surface.

Detailed geochemical sampling of springs and wells throughout the southern Harney Basin is needed before a realistic thermal-regime model can be attempted. This is apparent in a cursory examination of estimated reservoir temperatures (Table 4), some of which are nearly 400^{o}C, which indicates that a large number of springs and wells have either reacted strongly with wall rock or mixed with meteoric or shallow evaporite-rich water while ascending.

GEOTHERMAL-GRADIENT AND HEAT-FLOW DATA*

The temperature-gradient and heat-flow results for the south Harney Basin are as shown in Table 5. Included in the table are the township/range-section and latitude and longitude location of each hole. In addition, the hole name, date of logging used, and collar elevation are included for each hole. The bottom hole temperature, maximum depth, corrected temperature gradient, and, where available, corrected heat flow are printed in blue on Plates I-IV. These values are also listed in the table, as are the depth interval and average thermal conductivity used for calculation of the gradient and heat flow. The values are given in SI units. To transform units, the following conversion factors were used: 1×10^{-6} cal/cm^{2}sec (HFU) = 41.84 mWm^{-2}, 1×10^{-3} cal/cm sec^{o}C (TCU) = 0.4184 Wm^{-1}K^{-1}, and 1^{o}C/km = 1 mKm^{-1} = 18.2^{o}F/100 ft. Corrected gradient and corrected heat flow are values for which the topographic effects have been removed. These are not significant for most of the sites studied.

The holes are ranked in terms of the quality of the gradient or heat-flow information: high quality (A), good quality (B), marginal quality (C), data with some problems (D), and data for which no useful temperature gradient or heat flow can be estimated (X). All thermal-conductivity measurements were made on cutting samples.

Most data in the south Harney area have been obtained in holes drilled as water wells or mineral exploration holes, so the thermal-conductivity values are estimated (parenthesis) or based on one or two cutting samples from surface spoil piles. Several holes were drilled and the results published by the USGS (holes S1, S2, S3, MR-1, and MR-2 in Sass and others, 1976). Holes prefixed BFZ-75 were drilled by DOGAMI (BR-75 holes in Hull and others, 1976). The background gradient and heat flow for the area are about 60-80^{o}C/km and 60-80 mWm^{-2}. Several anomalous

holes are found near Coyote Buttes (Bowen and others, 1976), and hole BFZ-7504 near the southern part of the Basin has a very high heat flow (Plate IV).

CONCLUSIONS AND RECOMMENDATIONS

The reconnaissance study performed for the southern Harney Basin has tentatively identified two geothermal resource areas based on geology, geophysics, geochemistry, and sparse geothermal-gradient data. They are (1) the area surrounding the town of Crane (Plate II) and (2) the area immediately surrounding Harney Lake (Plates I, III, and IV). Preliminary results indicate both of these areas may have reservoir temperatures in the moderate range (100-150^{o}C). Site-specific analyses of these two areas should be carried out in one field program and include the following recommendations:

1. Detailed (scale of 1:24,000 or less) geologic and photogeologic mapping of Crane and Harney Lake geothermal areas -- to identify and evaluate active thermal structures and areas of recent hydrothermal alteration.
2. Detailed sampling and analysis of hot and cold springs and wells, including isotope and gas analyses -- to determine fluid flow directions and provenance and to determine precise reservoir conditions.
3. Closely spaced complete Bouguer and residual gravity anomaly studies -- to delineate possible active thermal structures or intrusives below surface units.
4. Several resistivity traverses (either dipole-dipole, roving dipole, or telluric) normal to mapped structures -- to further define the thermal regime.
5. A micro-earthquake/contemporary seismic study of the entire Harney Basin, making use of a high-gain seismometer array -- to define the seismicity of the area in relation to geothermal systems.
6. A program of twenty to thirty 500-ft gradient/stratigraphy holes, followed by a program of five to ten 2,000-ft holes -- to model heat flow and directly test geothermal aquifers.

APPENDIX A

Formulas used in calculations

Na:K (revised):

$$t\ ^{o}C = \frac{1217}{\log (Na/K) + 1.483} - 273.15 \text{ (Fournier, 1979)}$$

Na:K:Ca:

$$t\ ^{o}C = \frac{1647}{2.24 + F\ (T)} - 273.15 \text{ (Fournier and Truesdell, 1973),}$$

where $F\ (T) = \log (Na/K) + [\ \beta \log (\sqrt{Ca}/Na)\ ]$,
β = 1/3 if t> $100^{o}C$, and 4/3 if t <$100^{o}C$,
$t^{o}C$ = calculated reservoir temperature,
and concentrations are expressed in molality.

Magnesium correction ratio:

$$R = \frac{\text{(milliequivalents Mg)}}{\text{(milliequivalents Mg) + (milliequivalents Ca) + (milliequivalents K)}} \times 100$$

If R <5 or >50, no calculation was made. For R between 5-50,

$$\Delta t_{Mg} = 10.66-(4.7415)\ (R) + [(325.87)\ (\log R)^2] - [(1.032 \times 10^5)\ (\log R)^2/T] - [(1.968 \times 10^7)\ (\log R)^2/T^2] + [(1.605 \times 10^7)\ (\log R)^3/T^2],$$

where R = magnesium correction ratio expressed in equivalents,
Δt_{Mg} = the temperature correction that is subtracted from the Na:K:Ca 1/3 β calculated temperature,
T = Na:K:Ca 1/3 β calculated temperature in ^{o}K.

Or Δt_{Mg} can be obtained by using the graph compiled by Fournier and Potter (1979).

SiO_2 temperature calculations (Fournier and Rowe, 1966):

SiO_2 (conductive), $$t^{o}C = \frac{1309}{5.19 + \log (SiO_2)} - 273.15$$

SiO_2 (adiabatic), $$t^{o}C = \frac{1522}{5.75 + \log (SiO_2)} - 273.15$$

SiO_2 (chalcedony), $$t^{o}C = \frac{1032}{4.69 + \log (SiO_2)} - 273.15$$

SiO_2 (opal), $$t^{o}C = \frac{731}{4.52 + \log (SiO_2)} - 273.15,$$

where SiO_2 is expressed in mg/l.
